Short title: Nudging food position – a systematic review

Key words: Nudging, choice architecture, position, proximity, order, systematic review, food choice, environmental influences, nutrition policy, eating behaviors
Abstract

Nudging or ‘choice architecture’ refers to strategic changes in the environment that are anticipated to alter people’s behaviour in a predictable way, without forbidding any options or significantly changing their economic incentives. Nudging strategies may be used to promote healthy eating behaviour. However, to date the scientific evidence has not been systematically reviewed to enable practitioners and policy makers to implement, or argue for the implementation of, specific measures to support nudging strategies.

This systematic review investigates the effect of positional changes of food placement on food choice. Seven scientific databases were searched using relevant key words to identify interventions that manipulated food position (proximity or order) to generate a change in food selection, sales or consumption, amongst normal weight or overweight individuals across any age group. From 2576 search identified, 15 papers comprising 18 studies met the inclusion criteria.

This review has identified that manipulation of food product order or proximity can influence food choice. Such approaches offer promise in terms of impacting on consumer behavior. However, there is a need for high quality studies that quantify the magnitude of positional effects on food choice in conjunction with measuring the impact on food intake, particularly in the longer term. Future studies should use outcome measures such as change in grams of food consumed or energy intake to quantify the impact on dietary intake and potential impacts on nutrition related health. Research is also needed to evaluate potential compensatory behaviors secondary to such interventions.
Introduction

In recent years there has been shift away from solely targeting individuals to change their eating behaviours, to an approach that addresses wider, population-level factors, and involves other environmental components and stakeholders \(^1\). Foodscape \(^2\) and food environments contribute to the so-called “obesogenic environment” \(^1, 3\) and influence food choices. Epidemiological data suggests that numerous small changes towards a healthier behaviour, such as improving diet quality, have the potential to have a positive impact on reducing mortality risk \(^4\). Most healthy eating interventions in Europe have been successful in providing consumers with information to enable them to make better-informed food choices \(^5\). While they have been successful in creating awareness among consumers, there has only been modest success in terms of actual lifestyle changes and measurable health indicators in the sample populations, such as weight reduction \(^6\). Individualised behaviour change is ineffective unless it becomes habit-forming, which requires support and reinforcement through structural or environmental change so that the new behaviour is sustained. Although behavioural economics have impacted on some policy interventions, the case for food related interventions remains under development, constituting a promising area that could potentially achieve high social benefits \(^7, 8\).

Therefore, innovative intervention strategies that are able to effectively improve food behaviours, dietary intake and impact on health status need to be investigated and implemented. The majority of interventions have an underlying assumption that people make conscious and reasoned food choices, most of the time \(^9\). This paradigm has been questioned following the limited impact of information based campaigns in achieving behaviour change, and the subsequent rise in the prevalence of obesity and other chronic diseases \(^10\). Furthermore, current paradigms place the burden and responsibility for all food choices on the individual, with the justification that everyone is free to make healthy choices once informed \(^6, 11\).

Dietary habits and food choices are the result of decisions and actions that are based on routines that require very little active decision-making as well as reflective, elaborate decision-making where choice options are carefully considered. Choice architecture, inspired by behavioural economics, describes the way in which decisions are influenced based on how choices are presented within meal environments \(^12\). The meal environment has been defined as the room, the people, the food, the atmosphere and the management system, particularly when eating out-of-home. This suggests that
the meal environment can be modified to be more or less conducive to supporting the
required behaviour and, as such may lead to weight changes, either through promotion
of healthier choices or decreased intake\(^{(12-15)}\).

Choice architecture is often used interchangeably with other terms such as nudging,
libertarian paternalism and behavioural economics. Choice architecture is a subset of
non-regulatory behavioural interventions. Choice architecture can include one or more
of the following: provision of information (e.g. to activate a rational choice), changes
in the physical environment (e.g. light, décor, placement, etc.), changes in the default
policy (e.g. pre-weighed salad portions vs. free serving of a salad bowl) and, use of
social norms and salience (e.g. comparison with average consumers)\(^{(16)}\). Nudging has
been defined as any aspect of the choice architecture that alters people's behaviour in
a predictable way without forbidding any options or significantly changing their
economic incentives\(^{(15)}\). Within the public health nutrition area this could mean
altering the food environment, such as product placement or labelling or even
encouraging consumers to sit together for their meal (social facilitation). Furthermore,
nudging interventions consist of provision of information, changes to physical
environment, changes to the default policy and the use of social norms and salience
\(^{(16)}\).

Previous studies have shown that nudging practices are promising measures that can
be used to support the promotion of healthy eating. An example of nudging is that by
changing the size of dishware, portion sizes may be reduced leading to unconscious
changes in actual food intake\(^{(17)}\) and meal composition\(^{(18)}\). Similarly, food
positioning is thought to influence food choice. Studies have shown that people eat
more unhealthy food, such as chocolate if it is located more prominently\(^{(19)}\).
However, it is less clear, whether minor changes in food position or item placement,
which are not accompanied by changes in effort, also promote healthier food choices
\(^{(13, 20)}\).

Existing systematic reviews, which have investigated the effectiveness of choice
architecture interventions, mainly focused on the effectiveness of labelling and
prompting (see for example\(^{(21, 22)}\)). However, these types of interventions are more
closely related to the traditional behavioural interventions of information-giving\(^{(23)}\).
To date, there is no systematic review that has assessed the influence of food
placement within microenvironments on product choice and on food intake\(^{(23)}\). This
information is relevant for the support of public health interventions and relevant for operations in the foodservice sector.

The aim of this systematic review was to evaluate the published research that investigated the effect of positional changes within micro-environments on food choice by healthy weight and overweight individuals across all age groups, and to derive recommendations for future research in the area.

For the purpose of this review, we have defined a nudging intervention as any intervention that involves altering the non-economic properties, or placement of objects or stimuli within micro-environments with the intention of changing health-related behaviour. Such interventions are implemented within the same micro-environment in which the target behaviour is performed and require minimal conscious engagement. In principle, these interventions can influence the behaviour of many people simultaneously, and they are not targeted or tailored to specific individuals (adapted from (23)). The present review focuses on positional changes that affect immediate food consumption or choice decisions of individuals (e.g. eating out of home in a food service outlet), rather than the consumption pattern of a family or a household over time, as it would be the case in ‘assortment structure’ experiments within supermarket settings.

Methods

Details of the protocol for this systematic review were registered on PROSPERO and can be accessed at http://www.crd.york.ac.uk/PROSPERO/display_record.asp?ID=CRD42015016277

Criteria for study inclusion

The PICOS (Problem, Intervention, Comparison, Outcome, Setting) approach (24) was used to frame the research question. We defined ‘food choice’ as all outcome measures that assessed food selection or probability of food choice, including product sales and food consumption (in grams or energy intake). Positional changes were defined as all manipulations of food order or variations in the distance of food placement relative to consumers within microenvironments. Microenvironments were
defined as the immediate surroundings of the individuals, such as within the home, workplace, or cafeterias (25).

The types of studies to be included were randomised controlled trials/ experiments, pre-post experimental studies, quasi experiments and naturalistic observations where at least one research aim was to assess the influence of food positioning within a microenvironment, on food choice (selection) or sales (grams, number) and intake (grams, energy).

Studies where multiple variables were manipulated simultaneously along with the food position were not included. For example, studies where foods were added or removed from the selection or where portion sizes of healthy or unhealthy offers were altered along with a positional change were excluded. Study participants included only healthy normal weight or overweight/obese individuals. There was no age restriction with studies on both children and adults included. The search included full-text articles that were published in peer-reviewed journals in the English language.

Literature search

A systematic search was conducted using electronic databases (Medline, Pre-Medline, Embase, CINAHL, Scopus, The Cochrane Library and PsycINFO) until February 2015. No limit was placed on publication date. The search term list included the following items: choice architecture OR accessib*OR nudg* OR position* OR (serving AND (direction OR distance)) OR proximity OR distance AND food OR diet OR food choice OR energy intake OR caloric restriction OR fruits OR vegetables OR health* OR food choice. Reference lists of included articles and key reviews in the area were also manually searched for additional articles.

Review procedure

Two independent reviewers (TB and NdV/DvdB) screened the titles and abstracts of all search results. Full-text of all papers that appeared to potentially meet the inclusion criteria were retrieved. The retrieved full-texts were assessed by two independent reviewers (TB and NdV) to determine inclusion. In case of disagreement a third independent reviewer made the final decision (MR).

Data extraction and synthesis
Quantitative data on study participants (age, gender, weight status), the design (type of study, setting, manipulated variables) and the outcomes (finding, main effect, conclusions), from the included articles data was extracted by TB and checked by MR. To distinguish between the magnitude of the change in effort that was involved in the intervention, we differentiated between minor changes (mere order change or very small distance change within reach), medium (change of position to food that required only a small effort; e.g. standing up, bending down) or major positional changes (manipulations that involved a major increase/reduction in effort, e.g. walking across a room).

Quality assessment of included studies

The quality of the included studies was assessed by two independent reviewers (TMcC and HT) using the review evidence analysis manual published by the Academy of Nutrition and Dietetics (26). The quality scores can be found in the supplementary material (Table S1).
Results

The database search identified 2540 unique entries, which were combined with another 36 articles of interest that were identified by screening reference lists. A total of 62 full-text articles were retrieved and assessed against the inclusion criteria. Fifteen articles, comprising 18 studies met the inclusion criteria and the data of these was extracted and evaluated in this review (see Figure 1).

The majority (n=10) of the studies were conducted in the United States. Seven were conducted in Europe, of which four were conducted in the Netherlands. In one study, the country was not reported (27). There was only one study in children (28). Ten studies were conducted with university students or staff and for five studies the subjects were customers of hospital cafeterias. One was conducted in an army research centre (29) and one was conducted with attendees of a health conference (30).

The foods involved in the studies varied and included single healthy or unhealthy items (water, fruit and vegetable, cereal bars, chocolate candy or crackers) to more complex selections within canteens buffets with between eight and eleven products repositioned.

Seven studies reported participants’ weight status, however only two considered it in the analysis (27, 31). Levitz (27) reported that a change in dessert order affected normal and overweight people differently. In particular the author found that obese adults selected a greater amount of low-energy dessert if it was made more salient. No changes were observed if the high-energy desserts were made more salient (27).

The characteristics of the included studies are summarized in Table 1. Of the eighteen studies that were included, only one received a positive quality rating (32) with 14 studies being assessed as neutral, and three as negative because study procedures were not described in detail and several validity questions could not be answered clearly (Table S1).

Of the 18 studies, nine investigated the effect of distance/proximity changes on food choice, such as placing unhealthy foods further from the consumer. The other half assessed whether changes in product order, such as for example the food sequence on a buffet could have a beneficial influence on food selection.

In summary, 16 of the 18 studies concluded that positional changes had a positive influence on food choice. The only two studies, which did not find an effect, manipulated the product order of snacks on a computer screen (Van Kleef Study 1), as
well as within a shelf at a checkout counter in a cafeteria (Van Kleef Study 2).

However, in the field study they found a trend towards sales of healthy food being
positively affected \(^{(32)}\).

It was not possible to quantify and directly compare the effect sizes of the included
studies, as the study designs were too variable. Most studies were randomised
controlled experiments and only one study used correlation analysis to study the
relationship between distance and snack selection \(^{(28)}\). This study found that the
distance from the serving bowl significantly predicted the number of crackers and
carrot slices consumed by children \(^{(28)}\).

Between subject experiments were the most common study design, while within
subject, repeated measures designs were rarely used. Only one study employed a
longitudinal design \(^{(33)}\), which was a follow up assessment of the intervention
described by Thorndike et. al. and was based on the same choice architecture
intervention \(^{(34)}\). Both of these studies were retained in the review because they had
assessed different outcome measures and were complementary.

Most studies assessed food selection or choice probability using Chi Square tests,
while only few studies objectively measured actual food intake in terms of food
weight (grams) or energy (kcal or kJ) content. The intervention description and
findings of the included studies are summarized in Table 2.

Discussion

Out of 18 studies where food position or order was manipulated, 16 showed a positive
effect on food choice, meaning the participants were nudged towards a more healthy
food choice. In the two experiments \(^{(32)}\) where positional changes had no impact on
food choice, the degree of manipulation was only a minor change in position, with all
the foods remaining within reach. This indicates that the strength of the effect appears
to depend on the type of positional manipulation (order vs. distance), as well as the
magnitude of the change, or how far away foods are placed.

One study assessed compensatory food choices \(^{(35)}\), showing that changes in position
resulted in compensatory choices within same food categories. Further, movement of
potato chips to a more distant location, and hence a reduction in chips selection, was
accompanied by an increase in starch selection choices among the foods that still
remained proximal \(^{(35)}\). For portion size changes, there is some evidence from
previous research that reducing offered portion sizes does not result in immediate compensation (36). However, in that particular study the intervention was conscious, and consumers' self-control was activated by having servers ask customers in a fast food restaurant, if they wanted to downsize portions. Other studies, in which the overall energy of a meal bundle for children was reduced, without the participants being aware, found that the overall energy intake was significantly reduced (37). More research on compensatory behaviours is required to implement effective interventions in practice.

The overall quality of the included studies was neutral. Only a few papers described the procedures sufficiently well to allow a clear evaluation of all validity questions. In particular, the questions that related to subject selection, recruitment procedures and comparison of study groups were unclear or not applicable. Studies were classified as unclear or not being free from bias due to the use of cash incentives or course credit being offered to participants. This may be an artefact of the naturalistic setting of the studies, such as universities and workplace canteens.

There is a lack of research that investigated long-term outcomes of positional interventions, and it’s not clear whether changes in product order or distance would have sustained effects. Specifically, it is unclear whether a potentially positive effect of a position change, such as placing healthy foods in obvious positions and very close to cafeteria check-out lines, would potentially diminish over time and that customers would return to selecting a favoured unhealthy snack. To investigate this, more studies need to be conducted that evaluate this. Changes in choice need to be assessed at different time points, ideally over several weeks and months e.g. using data from a customer loyalty card scheme to determine sustainability of the intervention.

Furthermore, only one study (38) assessed the effect of potential covariates such as food preferences, restrained or disinhibited eating styles, or health consciousness on the outcomes of position choice architecture interventions. It therefore remains unclear which individuals are susceptible to nudges. Further insight on these covariates, as well as potential influences of habit strength, is required to design effective interventions.

A reason for these data not being reported may be that it is important to ensure participants are not aware of the nudging intervention, and this is likely to be the reason most field studies did not collect this information from participants. One
method that could be used to address this limitation in future research would be to implement interventions within settings where customer loyalty cards are used to collect additional data on participants’ actual purchases. For this purpose, collaborations with industry or supermarket chains could be effective. This would also have the advantage that potential product price and positioning interactions could be assessed.

Previous literature suggests that nudges could be inexpensive approaches to positively impact behaviours (15). In the studies included in this review however, there were no calculations on potential costs and benefits. Factual data on previously hypothesised benefits are required to make effective recommendations for policy makers.

Only two studies differentiated between healthy and overweight consumers and whether positional interventions were different based on body weight (27, 31). They both concluded that the positional nudges were effective irrespective of weight status. Further, one study assessed socioeconomic status and reported that it had no influence on whether positional interventions were effective (33). These findings concur with previous literature, which suggest that nudging effects work via subconscious mechanisms and therefore have equal impact regardless of weight and socioeconomic status (39).

Food position can be manipulated by changing the order of food products or by changing the distance between the food and the consumer. Both of these nudges operate in different ways. The mediating factor for the effect of distance on choice is thought to be effort, while for change in order it is reported to be salience (38). Changes in order normally constitute only a minor change in effort, whereas changes in distance affect the effort required in order to obtain a food at various levels. However, more research is needed to evaluate these two aspects in detail. Future research should also clearly distinguish between studies that examine nudging in terms of food order versus food proximity or distance.

To date, very little is known about why positional nudges could be effective, and in particular, it remains unclear how effects are moderated. The dual-process model (40) states that human behaviour largely results as a function of two interacting systems: the reflective system, which generates decisions based on knowledge about facts and values; and the impulsive system, which elicits behaviour through affective responses. The first system requires cognitive capacity, while the second system requires no cognitive effort and is driven by feelings and immediate behaviours in response to the
Nudging is thought to operate mainly through the second, automatic system and affects all individuals equally. However, it remains to be elucidated whether, and how factors such as health consciousness, habits, or strong preferences for specific products interact with the effects. The research of Levy et al. (2012) suggests that once the social gradient effects are taken into consideration, there is still an effect towards the desired outcome in terms of food choices. This indicates that these interventions could be powerful and that cheap nudging interventions could potentially yield more than other elaborate expensive campaigns do. However, further research is required to explore this in detail.

It was not possible to conduct a meta-analysis of effect sizes as a wide range of outcome measures were reported across studies. Although the evidence that food position influences food choice was consistent across studies, it was not possible to evaluate the impact and effect size of these types of choice architecture interventions on actual food consumption and subsequent health outcomes. As has been advocated previously, harmonized indicators are required that would allow comparability between experiments or interventions. We therefore strongly recommend the use of energy (kJ/kcal) or weight (grams) as outcome measures of changes in food selection and/or intake in future studies.

Strengths and limitations

This is the first systematic review that has assessed the influence of position interventions (proximity and order) on food choice. In addition to the terms ‘nudging’ and ‘choice architecture’, we used search terms such as ‘distance’ and ‘position’. This strategy located many articles that were beyond the topic of interest such as access to fast foods outlets, but ensured that older literature published before the terms ‘choice architecture’ and ‘nudging’ became popular were included.

For the purpose of this review, we defined nudging as any intervention that involved altering the non-economic properties, or placement of objects or stimuli within microenvironments, with the intention of changing health-related behaviour (adapted from (23)). We acknowledge that varying definitions of this term exist and that a disparate definition of the term might have led to the inclusion of different studies and hence influence the conclusions drawn.

Literature investigating the effect of the assortment structure on buying behaviour within supermarkets was not identified with the present search strategy. The authors
are aware that supermarket related shopping behaviour has been extensively described in the marketing literature, and that it is one of the venues where behavioural interventions may have a socially relevant outcome (7,41). This aspect was beyond the scope of the present study, which focused mainly on out-of-home meal service situations like cafeterias or canteens. Factors affecting selection at the time of consumption and the time of purchase may differ in this situation. In addition, it is relevant to note that there could be differences between nudges that aim to increase or decrease consumption, as well as between nudges that promote the choice of healthy foods versus nudges that discourage the consumption of unhealthy foods. As an example, it might be easier to promote the consumption of more (healthy) food, compared to discouraging the consumption of unhealthy (or preferred) food by positional changes. Studies in which the position of unhealthy and healthy foods are simply switched are particularly problematic, as they lack a neutral control group, which would enable researchers to disentangle whether there was a potential bias in effectiveness of nudging depending on the food. In the present literature, studies that strategically investigated the efficacy of the positional intervention depending on food type are missing. This review did not specifically consider any grey literature. Given the heterogeneity and the limited number of studies retrieved via the search strategy, it is plausible that a positive publication bias exists, although this was not assessed by the authors. It is interesting to note that the paternalistic nature of the concept of nudging has been discussed. In particular, it can be argued that a positional change that results in high effort to obtain an unhealthier food may be seen as a reduction in freedom of choice (42-45). However, owing to the ethical nature of this discussion, it is beyond the scope of this review.

The synthesis of the study findings was undertaken in a narrative format as the data aggregation was limited by the heterogeneity of the research in this field. Nevertheless, the current review identified gaps in the existing literature and where further research is needed.

Recommendations for laboratory studies
Although laboratory settings are limited, well-planned experiments could give insight on the strength of positional effects and therefore help to estimate the cost effectiveness of choice architecture interventions in practice, particularly if repeated measures are applied. Laboratory settings allow the follow-up of the same individuals for data collection. Quantifiable outcome measures such as change in energy (kJ/kcal) or weight (grams) of food selection or consumption should be used. Strong experimental evidence, including estimations of the potential health benefits secondary to a reduction in energy intake or consumer weight loss over time are needed to inform policy makers in terms of implementing choice architecture interventions in public health settings.

Recommendations for field experiments

Although previous research suggested that substitution might occur within the same product category following a choice architecture intervention, a trial in the Belgian city of Ghent showed that meal choices were not compensated for later in the day. Hence, future research should address the issue of compensation at the design stage and consider that compensatory behaviours could occur after a nudge intervention. As for laboratory settings, we also strongly recommend the use of energy or grams of food selected/consumed as an objective outcome measure, to estimate effect sizes and potential health benefits.

Furthermore, insight into factors (e.g. preferences, habit strengths, health consciousness) that potentially influence the effectiveness of positional interventions could be gained by collecting more information on customers in cafeteria-style settings, for example via a loyalty card scheme. This would further allow exploration of the sustainability (decay of effect over time, or potential compensatory choices) over time in these settings.

Reporting Recommendations

The 18 studies included in this review did not consistently describe the choice architecture intervention that was being assessed, for example whether ‘the nudge’ was a change in distance or in product positioning. On the other hand the inclusion of the distance in combination with food resulted in a large number of search results that were not relevant for the purpose of this study.
We suggest that standardised keywords and vocabulary could assist this field of research. Researchers should carefully consider the wording for their reports and could adopt the terminologies suggested by Hollands et. al. to classify choice architecture interventions (23) more clearly.

Advice for practice (policy makers, food retailers)

Choice architecture recommendations could support existing dietary guidelines, and so potentially contribute to the adherence and compliance. Although more research is required to quantify the magnitude of positional influences on health outcomes, it is evident that choice architecture is important and that food retailers influence consumption by organizing and displaying their products. Therefore, persons in charge of food organization or food outlet design (e.g. workplaces) need to be aware of their responsibility to organize “foodscapes” in an optimal way, for example to stimulate consumption of healthy foods and to reduce the consumption of unhealthy foods that then could support healthy workplace initiatives. In practical terms this means that low energy, nutrient dense products, such as fruits and vegetables should be placed in easy accessible and prominent positions. This is particularly applicable in large self-serving setting such a school or work canteens or the canteens of residences for the elderly.

Policymakers could integrate choice architecture nudging measures to augment their existing policy documents, as an important measure to enhance the effectiveness of healthy eating policies and procedures. In particular, this review provides evidence for policy makers, and specifically supports the use of positional changes as an effective manner to alter food choice in a desirable way.

Furthermore, the results of this review could be used for developing official recommendations regarding the implementation of choice architectural nudge interventions, and to harmonise the indicators for evaluation of the effect. A good practice example would be to place salad at the beginning of the buffet in school canteens in those countries where meals are provided at school.

Conclusions
Although the evidence that food position influences food choice is consistent, it is difficult to quantify the magnitude of impact on food choice and intake and the effect size of these choice architecture interventions on actual food consumption and subsequent health outcomes. Use of harmonized terminology and indicators would allow comparability between experiments or interventions and assist in moving this field forward.

Acknowledgments

We would like to thank Debbie Both for assistance with developing the search strategy and the database searches.

Financial support

TB received a fellowship from the Swiss National Science Foundation (P2EZP1_159086) and the SFEFS to work on this project. CEC is supported by an NHMRC Senior Research fellowship. APC is supported by: IAPP-Marie Curie FP7/EU grant (agreement # 612326 VeggiEAT).

Conflict of interest: The funding sources had no influence on the design of the study. There is no conflict of interest.

Conflict of Interest

None.

Authorship

TB, NdV and DvB screened the abstracts, TB and MR extracted the results, TMcC and HT performed the quality assessment. TB and APC jointly wrote the manuscript under incorporation of critical input from CC, HT, MR and TMcC.

<tr>
<td>Engell et. al., 1996</td>
<td>Water pitcher on table, vs. dispenser at 20ft or 40ft distance</td>
<td>Customers in Army research centre dining hall</td>
<td>Major; variation in proximity. Large increase in effort to obtain water at a dispenser across room or in another room</td>
<td>Water</td>
<td>ANOVA</td>
<td>Water consumption (gram)</td>
<td>Significant main effect of proximity on intake: $F_{(2,33)}=8.4, p&lt;.001$, Post hoc tests: significant reduction for distant conditions compared to proximate condition, no difference between the two more distant conditions.</td>
<td>Major reduction of water intake if dispenser is further away (on table vs. 20 or 40 feet). No difference between 20ft and 40ft. No effect on other food intake</td>
<td>Effort to obtain water determined amount consumed</td>
</tr>
<tr>
<td>Maas et al., 2012 (Study 1)</td>
<td>Distance to snack bowl was varied at 20, 70 and 140 cm</td>
<td>Staff/students recruited to laboratory on University campus</td>
<td>Medium; 70 cm and 140 cm proximity variation required standing up</td>
<td>Candy: Chocolate M&amp;M's (without peanuts) 1kg</td>
<td>Logistic regression, ANCOVA (control for chocolate liking)</td>
<td>Amount of snack consumed (gram) and risk of compensatory behaviour</td>
<td>Significant main effect of proximity on intake: $F_{(2,73)}=7.59, p=.001$, Post hoc tests: significant reduction for distant conditions compared to proximate condition, no difference between the two more distant conditions.</td>
<td>An increase in distance had a significant effect on the probability of snack consumption even for an increase from 20 to 70 cm. No effect for compensatory eating was found.</td>
<td>Distance affected intake, but salience did not.</td>
</tr>
<tr>

<td>Medium: 20, 70 and 140 cm. 70 and 140 cm required standing up</td>
<td>Candy: Chocolate M&amp;M's (without peanuts) 1kg</td>
<td>ANOVA</td>
<td>Amount of snack consumed (gram), perception of salience and effort, likelihood of consumption</td>
<td>Significant main effect of proximity on intake: $F_{(2,51)}=3.8, p=.029$, Post hoc tests: significant reduction for distant conditions compared to proximate condition, no difference between the two more distant conditions.</td>
<td>An increase in distance had a significant effect on the probability of snack consumption even for an increase from 20 to 70 cm. Perceived effort increased in distant conditions but not salience.</td>
<td>Sign. Effect of proximity on intake. Perceived effort was higher in the two distant conditions, but not perceived salience.</td>
</tr>
<tr>
<td>Meiselman et. al., 1994 (Study 1)</td>
<td>Move candy from cash point to distant snack bar.</td>
<td>Customers (students) of University cafeteria</td>
<td>Major; increase of distance (20 meters) and waiting at separate queue. Plus reduction in availability, (from four cash registers to one snack bar)</td>
<td>9 Food categories; Main dishes; pizza, alternatives, salads, sandwich, Desserts:, fruit, accessory foods, Candy; chocolate, chocolate containing bars and muesli bars</td>
<td>Binominal model (Chi-Square)</td>
<td>Candy selection with meals (selection rates)</td>
<td>Less candy selected in nudging condition: $\chi^2(1)=17.78, p&lt;.001$. Trend towards more total desserts: $\chi^2(1)=2.21, p&lt;.1$ (ns), no effect on other foods</td>
<td>Less candy was purchased during the intervention week. However, participants who chose candy in the first week chose more dessert fruit or accessory foods during the intervention week.</td>
<td>Major increase in effort to obtain an unhealthy food can reduce the consumption of the food. People may partially compensate unhealthy choices.</td>
</tr>

<tr>
<td>Meiselman et. al., 1994 (Study 2)</td>
<td>Move potato chips from cash register to distant snack bar.</td>
<td>Customers (students) of University cafeteria</td>
<td>Major; increase of distance (20 meters) and waiting at separate queue. Plus reduction in availability, (from four cash registers to one snack bar)</td>
<td>11 Food categories; Main meal, pizzas, starch, vegetables, salads, bread, sandwiches, dessert, fruit, crisps, sweets/cakes, sauces, candy, drinks</td>
<td>Fleiss's formula and chi-square tests</td>
<td>Potato chips selection with meals (selection rates)</td>
<td>Less potato chips selected in nudging condition: $\chi^2(1)=77.27, p&lt;.001$. More starch foods during intervention: $\chi^2(1)=6.20, p&lt;.001$</td>
<td>Increased effort reduced potato chips selection, reduction was accompanied by increased starch selection</td>
<td>Varying effort can increase or decrease consumption. Foods are substituted with other foods (within same food group)</td>
</tr>
<tr>
<td>Musher-Eizenman et. al., 2010</td>
<td>Children were randomly placed at varying distances to healthy and unhealthy snacks</td>
<td>Children in day care</td>
<td>Major: children had to stand up and come up to the experimenter from varying distances and ask for more snack</td>
<td>Snacks: High energy dense animal crackers vs. carrot slices</td>
<td>Hierarchical regression</td>
<td>Consumption of crackers and carrot slices (number of pieces consumed)</td>
<td>Distance from serving bowl predicted intake Distance from crackers: $\beta=-.41, p&lt;.05$ ($\Delta R^2=.17$), distance from carrots $\beta=-.38, p&lt;.05$ ($\Delta R^2=.14$)</td>
<td>Distance from the serving bowl significantly predicted number of crackers and carrot slices consumed</td>
<td>Proximity influences consumption of healthy and unhealthy snacks in children</td>
</tr>

<tr>
<td>Privitera et al., 2012</td>
<td>Manipulation of proximity (near vs. far) and visibility (clear vs. opaque bowl) of healthy foods</td>
<td>Students recruited to laboratory on University campus</td>
<td>Medium: Serving bowl placed 2 metres away on counter or on table within arm’s reach</td>
<td>Snacks (healthy): fruits and vegetables</td>
<td>ANOVA</td>
<td>Apple and carrot consumption (number of pieces consumed)</td>
<td>Significant effect of distance on intake: Apple: $F_{(1,44)} = 25.46, p &lt; .001$ Carrots: $F_{(1,44)} = 4.52, p &lt; .04$</td>
<td>Proximity increased intake of both, fruit and vegetable intake (Visibility only affected of fruit intake).</td>
<td>Proximate can increase consumption of healthy foods. The effect was stronger for apples compared to carrots. This might be because fruits are sweeter and more appealing than vegetables. Making a low calorie food more proximate than a high calorie food, will reduce total energy intake, even if a high calorie and more preferred food is also available but less proximate</td>
</tr>
<tr>
<td>Privitera et al., 2014</td>
<td>Effect of proximity was tested in a competitive food environment with healthy food and unhealthy food at different distances</td>
<td>Students recruited to laboratory on University campus</td>
<td>Medium: Two meters vs. arms reach</td>
<td>Snacks: Apple slices (healthy food) vs. buttered popcorn (high fat/unhealthy food)</td>
<td>ANCOVA: BMI as covariate</td>
<td>Apple and popcorn consumption (kcal and proportion)</td>
<td>Proximity influenced intake: Popcorn: $t_{(17)} = 4.96, p &lt; .001$ Apple: $t_{(16)} = 5.16, p &lt; .001$ Significant interaction of proximity and food type $F_{(2,52)} = 16.46, p &lt; .001, R^2 = .38$</td>
<td>The food that was placed closer to the participants was consumed most, regardless of preference</td>
<td>More candy consumed if it is more proximate</td>
</tr>
<tr>
<td>Wansink et al., 2006</td>
<td>Manipulation of proximity (near vs. far) and visibility (clear vs. opaque bowl) of candy</td>
<td>Female staff within their offices at University</td>
<td>Medium: two meters vs. arms reach</td>
<td>Candy (individually wrapped chocolates)</td>
<td>ANOVA, (post hoc t-tests)</td>
<td>Chocolate consumption (number of pieces)</td>
<td>1.8 chocolates more consumed if they were proximate. Effect size unclear.</td>
<td>More candy consumed if it is more proximate</td>
<td>Proximity increases consumption. People overestimate consumption of less proximate foods.</td>

   - Yes
   - No
   - Yes
   - Yes
   - Yes
   - Yes
   - Yes
   - Yes
   - Yes

7. Were outcomes clearly defined and the measurements valid and reliable?*
   - Yes
   - No
   - Yes
   - Yes
   - Yes
   - Yes
   - Yes
   - Yes
   - Yes

8. Was the statistical analysis appropriate for the study design and type of outcome indicators?
   - Unclear
   - No
   - Yes
   - Yes
   - Yes
   - Yes
   - Yes
   - Yes
   - Yes

9. Are conclusions supported by results with biases and limitations taken into consideration?
   - Yes
   - No
   - Yes
   - No
   - Yes
   - Yes
   - Yes
   - Yes
   - Yes

10. Is bias due to study’s funding or sponsorship unlikely?
    - Unclear
    - Unclear
    - Yes
    - Yes
    - Unclear
    - Yes
    - Yes
    - Yes
    - Yes

**Notes.** Legend study quality scores: (+) positive, (-) negative, Ø neutral. N/A – Not applicable.
* For human studies to be graded as positive, questions 2, 3, 6 and 7 needed to be graded as “Yes” plus one additional criteria
