Transcriptomic analyses have identified tens of thousands of intergenic, intronic, and cis-antisense long noncoding RNAs (lncRNAs) that are expressed from mammalian genomes. Despite progress in functional characterization, little is known about the post-transcriptional regulation of lncRNAs and their half-lives. Although many are easily detectable by a variety of techniques, it has been assumed that lncRNAs are generally unstable, but this has not been examined genome-wide. Utilizing a custom noncoding RNA array, we determined the half-lives of ~800 lncRNAs and ~12,000 mRNAs in the mouse Neuro-2a cell line. We find only a minority of lncRNAs are unstable. LncRNA half-lives vary over a wide range, comparable to, although on average less than, that of mRNAs, suggestive of complex metabolism and widespread functionality. Combining half-lives with comprehensive lncRNA annotations identified hundreds of unstable (half-life < 2 h) intergenic, cis-antisense, and intronic lncRNAs, as well as lncRNAs showing extreme stability (half-life > 16 h). Analysis of lncRNA features revealed that intergenic and cis-antisense RNAs are more stable than those derived from introns, as are spliced lncRNAs compared to unspliced (single exon) transcripts. Subcellular localization of lncRNAs indicated widespread trafficking to different cellular locations, with nuclear-localized lncRNAs more likely to be unstable. Surprisingly, one of the least stable lncRNAs is the well-characterized paraspeckle RNA Neat1, suggesting Neat1 instability contributes to the dynamic nature of this subnuclear domain. We have created an online interactive resource (http://stability.matticklab.com) that allows easy navigation of lncRNA and mRNA stability profiles and provides a comprehensive annotation of ~7200 mouse lncRNAs.

[Supplemental material is available for this article.]

High-throughput studies of mammalian genomes have revealed that most of the genome is transcribed in a complex manner, including the production of tens of thousands of long non-protein-coding RNAs (lncRNAs) (Carninci et al. 2005; Birney et al. 2007; Guttman et al. 2009, 2010). Despite rapid progress, only a small proportion of lncRNAs have been functionally characterized (Amaral et al. 2011), and little is known about most lncRNAs. One particularly poorly understood aspect of lncRNAs is their post-transcriptional regulation and metabolism in the cell. Despite an absence of genome-wide studies to examine lncRNA stability, it has been a general expectation that lncRNAs will be less stable than protein-coding mRNAs, both due to their lower average level of expression and the existence of known unstable classes of lncRNAs (Dinger et al. 2009a). These classes, including cryptic unstable transcripts (CUTs) in yeast (Wyers et al. 2005), upstream non-coding transcripts (UNTs) in Arabidopsis (Chekanova et al. 2007), and promoter upstream transcripts (PROMPTs) in humans (Preker et al. 2008), have supported the suggestion that many, if not most, lncRNA transcripts are highly unstable (Houseley and Tollervey 2009). However, the stability of the small number of functional lncRNAs that have been determined (Sheardown et al. 1997; Seidl et al. 2006; Sone et al. 2007; Askarian-Amiri et al. 2011), suggest that lncRNAs, like mRNAs, have a wide diversity of half-lives. However, genome-wide methods, which provide a more objective view of lncRNAs as a class, are required to test this hypothesis.

Previous studies have investigated mRNA stability genome-wide using microarray technology and RNA sequencing (RagHAVan et al. 2002; Yang et al. 2003; Narsai et al. 2007; Friedel et al. 2009; Sharova et al. 2009; Rabani et al. 2011; Schwanhausser et al. 2011) but have not considered lncRNAs. These studies revealed a wide variation in stability between different mRNAs and its importance in combining with transcription to determine the steady-state levels of transcripts and also to control the speed and timing of changes in gene expression (Elkon et al. 2010; Rabani et al. 2011). For example, the low stability of groups of mRNAs, including those that encode transcription factors, is integral to their rapid dynamic regulation (Yang et al. 2003; Narsai et al. 2007; Friedel et al. 2009). Although changes in transcription are responsible for most dynamic changes in gene expression, changes in RNA stability also provide a mechanism to regulate gene expression levels (Blattner et al. 2000; Sharova et al. 2009; Rabani et al. 2011).

Here, we perform a genome-wide analysis of lncRNA stability using custom microarrays that examine ~7200 lncRNAs together with ~20,000 protein-coding transcripts. Although the average turnover of lncRNAs is higher than mRNAs, we find that lncRNAs display a wide range of stabilities comparable to that of protein-
coding transcripts. The functionally characterized lncRNA Neat1 was also found to be highly unstable, highlighting the notion that high turnover is not refractory to function and rather can promote the dynamic nature of lncRNAs and the cellular constituents with which they are associated.

Results

Genome-wide determination of RNA half-lives

To examine the stability of lncRNAs, we inhibited transcription in mouse Neuro-2a (N2A) neuroblastoma cells with actinomycin D (Hurwitz et al. 1962) and measured RNA levels over a 32-h time course. In the absence of transcription, the percentage of an RNA remaining is determined by its rate of decay. Use of an extended time course, similar to that conducted for mRNAs in Arabidopsis (Narsai et al. 2007), allows improved half-life measurements for transcripts with slow decay rates (Friedel et al. 2009) compared to previous transcriptional inhibition experiments in mammals that were continued to only 8 h (Raghavan et al. 2002; Yang et al. 2003; Sharova et al. 2009). We validated the transcriptional blocking methodology by determining the stability of the Myc oncogene mRNA, which is known to have a very short half-life (Dani et al. 1984; Raghavan et al. 2002), by qPCR. Consistent with previous observations, Myc mRNA was highly unstable (Fig. 1A) with a half-life of 33 min (95% confidence interval 25–48 min).

Genome-wide analysis of lncRNA stability was conducted using NCode (Life Technologies) microarrays, which contain probes that target ~7200 distinct lncRNA transcripts as well as probes that target most annotated protein-coding genes. As reported previously (Sharova et al. 2009), the most stable transcripts increased in relative abundance in samples from later time points and so give the artifactual appearance of up-regulation. Therefore, we normalized the scale of the array expression data to a pool of ultra-stable control transcript(s). Gapdh had been used to normalize shorter time courses in a previous study (Raghavan et al. 2002), but it is not stable over 32 h (Supplemental Fig. S1), and scaling to a single mRNA over a long time course could introduce noise. We recently identified the lncRNA Zfas1 (1500012F01Rik) as highly stable with no degradation over a 16-h time course (Askarian-Amiri et al. 2011) and were able to confirm by qPCR that its relative expression was virtually unchanged after 32 h (Fig. 1B). As expected, the microarray data showed a relative increase in Zfas1 expression by 32 h (Fig. 1C). Therefore, we selected six genes showing similar profiles to Zfas1 that also had previous evidence of high stability in mouse cells (Friedel et al. 2009). This high stability was confirmed by qPCR analysis of two of these mRNAs, Atp5e and Gstm1 (Supplemental Fig. S1), which showed little or no change in abundance over the time course. The average fold change between 0 h and each treated time point for these seven genes was adjusted to zero, and the intensity values of the probes were scaled proportionately to create the normalized time course data set.

We identified 14,987 transcripts that were expressed significantly above background (Supplemental Table S1), from which we calculated transcript half-lives by modeling each transcript with one-phase exponential decay or linear decay. As one-phase exponential decay is not optimal for modeling some highly stable transcripts, we calculated half-lives using both exponential decay and linear decay and selected the best model for each transcript (see Methods). Examination of transcript half-lives revealed that linear decay began to be favored for transcripts with half-lives above 18 h. After filtering to remove transcripts that could not be accurately modeled, we determined the half-lives for 12,670 transcripts (including 823 lncRNAs), (Supplemental Table S2). Examples of half-lives calculated from the microarray data are shown in Figure 1D–F.

Figure 1. RNA half-life determination following transcription inhibition. (A,B) Transcript decay curves after blocking transcription in N2A with actinomycin D and measuring transcript remaining relative to a control gene by qPCR. Error bars show standard deviation. (A) Myc decay relative to Gapdh. Gapdh is a suitable control gene for transcripts that are not highly stable. Results are from four biological replicates, which were subsequently used for microarray analysis. The fitted curve was modeled by one-phase decay using nonlinear least squares regression. Myc expression was also tested in mock treated time courses, which did not show evidence of transcript decay. (B) Transcript decay curve for Zfas1 relative to Atp5e. Results from three biological replicates. No degradation is observed, and nonlinear regression supports a horizontal line fit. (C) Zfas1 expression over 32-h time course following transcription inhibition from microarray. Four biological replicates; error bars show standard deviations. Nonlinear regression was used to test model fits and supports a linear fit with a positive slope showing apparent up-regulation of expression by 32 h. (D–F) Decay curves and half-lives determined for two random mRNAs (D,F) and one lncRNA (E) transcript from microarrays. All were modeled using one-phase exponential decay. Error bars represent standard deviations.
To confirm modeled transcripts were within the dynamic range of the arrays, we compared transcript half-lives with their expression values at 0 h. We did not observe increased half-lives at low expression levels, which could have suggested that array background was preventing the decay signal. This observation held true whether comparing all RNAs, or IncRNAs only (Supplemental Fig. S2). Indeed, there was a significant correlation (r = 0.2045, Spearman correlation) between higher expression and longer half-lives for all RNAs, but no correlation between IncRNA expression and half-life (Supplemental Fig. S2).

We validated that the arrays were sufficiently sensitive to detect unstable transcripts by comparing the calculated half-life for Myc as determined by qPCR to that determined by the microarrays, as well as the array stability of Znfx1, which we recently showed to be unstable in N2A cells by qPCR (Askarian-Amiri et al. 2011). The array-determined half-life of Myc was 34 min, which is in excellent agreement with qPCR, as was that of Znfx1 (65 min by array versus 50 min by qPCR). These data confirmed the accuracy of the array results and our ability to determine the half-lives of short-lived transcripts.

GO analysis of stable and unstable protein-coding genes

Previous studies have shown that unstable protein-coding transcripts are enriched for transcription factors, while mRNAs encoding proteins for various cellular metabolic processes are enriched amongst stable transcripts (Yang et al. 2003; Friedel et al. 2009; Sharova et al. 2009; Rabani et al. 2011). To assess the biological robustness of our data, we performed a GO analysis of protein-coding transcripts found within the unstable (half-life < 2 h) and highly stable (half-life > 12 h) fractions using Fatigo (Medina et al. 2010). Consistent with previous studies, we found that genes involved in transcription and regulation of gene expression were enriched in the unstable fraction, especially proteins with transcription factor activity, which were strongly overrepresented (P = 1.59 × 10^{-7}), while genes involved in numerous cellular metabolic processes and with oxidoreductase activity were enriched amongst the highly stable mRNAs (Supplemental Table S3). Together, these observations suggest our experimental model for RNA decay is applicable for making biologically relevant interpretations.

Stability of IncRNAs

To examine the stability of IncRNAs and how they compare to mRNAs, we graphed the distribution of half-lives. Figure 2A reveals that transcript half-lives ranged from <30 min to >48 h. IncRNAs show a similar range of half-lives to protein-coding transcripts, suggesting that IncRNA stability is a regulated process. The median IncRNA half-life was 3.5 h (mean 4.8 h), whereas the median half-life for protein-coding transcripts was 5.1 h (mean 7.7 h). This result shows that IncRNAs are not unstable as a class, although their half-lives are, on average, shorter than protein-coding RNAs (P < 0.0001) (Fig. 2A). We also find that a higher percentage of IncRNAs are classified as unstable (29% versus 17%) (t < 2 h; P < 0.0001) (Fig. 2B,C) and a lower percentage as highly stable (6% versus 17%) (t > 12 h; P < 0.0001) (Fig. 2B,D).

In total, we identified ~240 unstable IncRNA transcripts (t < 2 h). Although most IncRNAs are yet to be annotated, this group contains a number of known and functionally validated IncRNAs. These include Neat1 (see below), the probable mouse Adapt33 (s430416N029ik) homolog, a number of IncRNAs that associate with chromatin-binding proteins (Guttman et al. 2011) (see below), small RNA host transcripts including Mir17hg, an isoform of Rnst, and several snoRNA host genes including Snhg3, Snhg5, and one Snhg8 isoform, as well as the imprinted IncRNAs Kcnq1ot1 and Peg13. The low stability of several snoRNA host transcripts is in stark contrast to the extreme stability of Zfas1, which is also a snoRNA host gene.

Fifty-one IncRNAs had half-lives of over 12 h and were, therefore, classified as highly stable. These IncRNAs corresponded to a variety of genomic context classifications including intergenic, bidirectional with other transcripts, and intronic to protein-coding loci. Few have been characterized in detail with the exception of 4933436c209ik (Linc1399), identified as involved in maintaining pluripotency in embryonic stem cells, where it associates with the chromatin-binding protein CBX3 (Guttman et al. 2011). Given that we have characterized the stability of only a subset of the total number of IncRNAs, these results suggest that there are a large number of highly stable IncRNAs. Although the function of these transcripts is generally unknown, genes with enzymatic and housekeeping functions are enriched amongst stable protein-coding RNAs, so we hypothesize that housekeeping IncRNAs will also show high stability.

Clustering of RNA decay profiles

Transcripts of different stabilities provide a rich variety of decay profiles. To visualize these, we clustered all IncRNAs using supervised hierarchical clustering (Fig. 3). These results further reinforce the notion that IncRNAs are not generally unstable but rather show a wide range of stability profiles.

Previous analyses of coding transcript stability have revealed relationships between stability and gene function and that mRNAs...
that act in common biological pathways (same GO function) (Sharova et al. 2009) or proteins found within the same complexes (Friedel et al. 2009) often have similar stabilities. On this basis, we hypothesize that the stability of lncRNAs may be similarly related to their functional classes and that lncRNAs with related functions may tend to cluster together according to their stability profiles.

To reveal potential relationships between stability and function, we reclustered all expressed transcripts by their decay profiles using QAPgrid (Inostroza-Ponta et al. 2011). The decay profile for each individual cluster is shown in Figure 4. As a result of this optimization-based approach to visualization, the distance between each decay profile in the final layout is related to the difference between the decay profiles. From our data set of 14,987 decay profiles, the method produced 152 clusters, which, in turn, aggregate into seven “super-clusters” containing related decay profiles. The 152 clusters contain from 2 to 4447 transcripts. Most transcripts are found in a relatively small number of clusters, with 29.7% present in the single most populous cluster (Cluster 0), which is part of the largest super-cluster (Super-cluster 0). Indeed, the ten most populous individual clusters contain 79.9% of all transcripts, from the generally highly unstable transcripts in Cluster 1 (1087 transcripts) through to the extremely stable transcripts in Clusters 15 (196 transcripts) and 27 (797 transcripts). Hence, it appears that a reasonably small number of clusters and super-clusters can define the dynamics of RNA degradation.

To facilitate the browsing and visualization of transcript stabilities, we developed an interactive, web-accessible version of the QAPgrid representation of the clusters (http://stability.matticklab.com/). Each decay cluster is linked to a table of the transcripts it contains, together with their associated half-lives and further annotations including transcript classification, structural features, conservation, subcellular localization and expression information.

Comparing the annotated transcripts present in different super-clusters (i.e., independent of modeled half-lives) revealed a number of features overrepresented within individual super-clusters. For example, Super-cluster 1 showed an enrichment for genes encoding nuclear proteins ($P < 5.72 \times 10^{-66}$) involved in the regulation of transcription ($P < 4.40 \times 10^{-56}$) as estimated by g:profiler (Reimand et al. 2011), while a MEDLINE-based analysis using GATHER (Chang and Nevins 2006) revealed a significant enrichment of genes associated with the term “oncogene” ($P < 0.0003$) (Supplemental Table S4). Super-cluster 1 also had the highest proportion of lncRNAs (13.5%). Taken together these analyses demonstrate how QAPgrid clustering facilitates both the extraction of biologically meaningful data from, and visualization of, genome-wide data sets.

**Combining clustering and RNA half-lives to identify potentially independent transcripts**

The identification of transcripts from common loci with different half-lives or occurrence within different super-clusters provides a potential means to disentangle independent transcripts from complex loci. This is useful as such loci can contain numerous overlapping transcripts with alternative splice sites and varying start and end positions, which can be very challenging to distinguish.

We searched the four most populous super-clusters (0, 1, 3, and 5, containing 94% of clustered probes) for Unigene genes with multiple probes that clustered into more than two super-clusters. This analysis identified 21 genes (Supplemental Fig. S3; Supplemental Table S4). One gene identified was Tcf4 (transcription factor four). Two probes to constitutive splice junctions showed half-lives of 14.5 and 6.7 h, respectively, whereas three probes distributed across the 5-kb Tcf4 3’ UTR (Supplemental Fig. S4) all identified a half-life of 3.4–3.5 h. The high concordance and divergent half-life of the 3’ UTR suggests its regulation is independent of the common coding isoform, potentially due to processing of the 3’UTR (Mercer et al. 2011) or due to specific use of the 3’UTR by an alternative Tcf4 isoform. This differential stability across the gene locus would be difficult to detect by standard expression arrays or next-generation sequencing, but regulation of this nature is readily identifiable from transcript decay.

Another example that illustrates the value of stability profiling for disentanglement of transcripts is the noncoding snoRNA host gene Snlh4, which terminates ~4 kb upstream of the coding gene Matr3. Both cDNA cloning (Bortolin and Kiss 1998) and next-generation sequencing (Guttman et al. 2010) suggest Snlh4 is commonly a 5’ upstream start site for Matr3 (Supplemental Fig. S4). However, our data show that Snlh4 is unstable (and found in Super-cluster 1), whereas Matr3 is highly stable (and found in Super-cluster 5), suggesting that these transcripts can be distinct and independently regulated.
Genomic location impacts lncRNA stability

Previous studies have defined a number of sequence elements that influence mRNA stability (Yang et al. 2003; Narsai et al. 2007; Sharova et al. 2009). To further understand how lncRNAs differ in stability and why they are, on average, less stable than mRNAs, we investigated the relationship between lncRNA stability and their corresponding sequence elements and features.

To analyze various features that could affect lncRNA stability, we created a comprehensive set of genome-wide lncRNA annotations (Supplemental Table S2), which represent the most detailed annotations of mouse lncRNAs to date. An important feature of lncRNAs is the genomic location they are transcribed from in relation to protein-coding genes (Mercer et al. 2009). On this basis, lncRNAs can be broadly classified as intronic, where they originate from within coding gene loci, cis-antisense, where they are transcribed from the opposite stand to other transcripts, or intergenic, where they are transcribed outside of, or between, coding genes (Supplemental Fig. S5). Comparison of the stability of intergenic, intronic and cis-antisense lncRNAs revealed significant differences between the groups, with intronic lncRNAs less stable than those from intergenic regions or antisense to other transcripts ($P < 0.001$) (Fig. 5A) with a much greater percentage of intronic lncRNAs classified as unstable ($t_{1/2} < 2$ h) ($P < 0.0001$) (Fig. 5B,C), although there was no difference between the number classified as highly stable ($t_{1/2} > 12$ h) ($P = 0.34$, $x^2$ test).

LncRNAs can be transcribed from other genomic loci including bidirectionally (either head-to-head or tail-to-tail) with other transcripts (Engstrom et al. 2006), 3' from coding genes (uaRNAs) (Mercer et al. 2011) and from promoter regions (promoter-associated) (Preker et al. 2008) (Supplemental Fig. S5). Another subset of lncRNAs are large intergenic noncoding RNAs (lincRNAs) (Guttman et al. 2009, 2010), many of which have critical roles in differentiation and development (Guttman et al. 2011). We identified the half-lives for 90 transcripts from lincRNA regions, including LincRNA-p21 (Gm16197), which acts downstream from p53 (also known as TP53) to repress many genes (Huarte et al. 2010) and which was quite stable with a half-life of over 6 h.

Comparing all classes of lncRNAs revealed that intergenic, cis-antisense, tail-to-tail bidirectional and uaRNA transcripts are significantly more stable (on average) than intronic and promoter associated lncRNAs ($P < 0.01$) (Fig. 5D).
including modification of epigenetic state, alternative splicing, and RNA polymerase binding efficiency (Dinger et al. 2008; Khalil et al. 2009; Zhao et al. 2010; Amaral et al. 2011). Proteins with similar regulatory roles, such as transcription factors, typically have short half-lives and are nuclear-localized. Therefore, to identify lncRNAs with potential regulatory roles in the nucleus, we interrogated total RNA isolated from nuclear and cytoplasmic fractionated N2A cells with the NCode microarrays. Successful isolation of pure nuclei and cytoplasmic fractions was confirmed by qPCR and Western blot (Supplemental Fig. S7). The array data were validated by qPCR for a number of genes ranging from nuclear-specific to cytoplasmically enriched (Supplemental Fig. S8) and also by the high nuclear enrichment of known nuclear lncRNAs, such as Xist and Bace1as. Array analysis revealed 499 lncRNAs that were significantly enriched in the cytoplasm and 191 in the nucleus. Intersection with lncRNAs and lncRNAs listed in lncRNAdb revealed a number of known and uncharacterized localizations of lncRNAs, including nuclear enrichment of Adapt33, Zfas1, and several other snoRNA host genes. Taken together, these results support the widespread trafficking of lncRNAs to different subcellular locations.

Among the subset of lncRNAs for which a half-life could be determined, we identified 22 that were significantly enriched in the cytoplasm and 105 that were enriched in the nucleus. Nuclear-localized transcripts displayed a significantly lower stability (Fig. 5E) with a greater proportion (52%) of the nuclear-enriched transcripts classified as highly unstable ($P < 0.0001$, $\chi^2$ test) (t½ < 2 h) (Fig. 5F; Supplemental Fig. S9). In contrast, stable transcripts (t½ > 6 h) were not enriched in either compartment ($P = 0.26$, $\chi^2$ test).

We considered whether the unstable nature of nuclear-localized transcripts was due to an overabundance of unstable IncRNA genomic classes (intronic, promoter-associated, and head-to-head). Head-to-head transcripts were, instead, underrepresented in the nucleus ($P = 0.0154$, Fisher’s exact test). An increased prevalence of exosome-targeted transcripts similar to CUTs and PROMPTs could also help explain the low stability of nuclear transcripts; however, there was no enrichment for promoter-associated IncRNAs in the nucleus ($P = 0.74$, Fisher’s exact test) or among the unstable nuclear fraction ($P = 1.0$, Fisher’s exact test). Although intronic transcripts were enriched in the nuclear fraction ($P = 0.0005$, Fisher’s exact test), nuclear-localized intronic IncRNAs were less stable than those intronic IncRNAs not found in the nucleus ($P = 0.015$, Mann Whitney t-test). Taken together, these results suggest the impact on stability is due to the cellular location

### Figure 5.
Effect of lncRNA features on stability. (A) Comparison of the stability of intronic versus intergenic and cis-antisense IncRNAs. Box-and-whisker plot. (Whiskers) 1st–99th percentile, with individual transcripts outside this shown as dots. (Box) 25th–75th percentile. Difference calculated using one-way ANOVA with Kruskal-Wallis nonparametric test and Dunn’s post-test to compare individual annotations. (8) Frequency distribution showing the fraction of IncRNA transcripts in 2-h bins. Plotted points are at the center of the 2-h bin. Only time points with 1% or more of transcripts are plotted. (C) Percentage of unstable (half-life under 2 h) IncRNA intergenic, cis-antisense, and intronic transcripts. Significant difference calculated using $\chi^2$ test. (D) Comparison of the stability of all lncRNA genomic classifications. Box-and-whisker plot. To focus on the center of the distribution, whiskers show 10th–90th percentile, with individual transcripts outside this shown as dots, and only half-lives between 0.2 h and 20 h are shown. Significant differences found between stability of classes using one-way ANOVA with Kruskal-Wallis nonparametric test and Dunn’s post-test to compare individual annotations. (*) Level of significance common to all comparisons. (E) Comparison of the stability of localized transcripts. Box-and-whisker plot and statistical testing as per A. (F) Frequency distribution showing the fraction of nuclear, cytoplasmic, and nonenriched transcripts in 2-h bins. Plotted points as per B. (*) $P < 0.05$, (**) $P < 0.01$, (***) $P < 0.001$.
of these lncRNAs, rather than resulting from their genomic classification.

The relatively high turnover of nuclear-localized lncRNAs is consistent with the notion that these lncRNAs are acting as regulatory molecules, which, like their protein-coding counterparts, are turned over rapidly to provide a high degree of dynamism to the processes they regulate. We find preliminary evidence to support this hypothesis by investigating the stability of RNAs identified as interacting with chromatin-binding proteins (Amaral et al. 2011; Guttman et al. 2011), which are less stable than lncRNAs ($P = 0.049$, Mann Whitney $t$-test), more likely to be unstable ($P = 0.017$, Fisher's exact test), and more likely to be nuclear-localized ($P = 0.028$, Fisher's exact test).

LncRNA decay elements

A number of decay elements have been detected, predominantly in the 3'UTR, of mRNAs, including AU-rich elements (AREs) (Bakheet et al. 2001) and Puf family protein-binding sites (Xie et al. 2005). Spliced mRNA transcripts are more stable than single exon mRNAs (Narsai et al. 2007), and there are positive correlations between both the number of introns and the density of splice junctions per kb of ORF length and stability (Sharova et al. 2009). To investigate whether these factors known to affect coding transcript stability also impact the stability of noncoding RNAs, which would suggest common regulatory and decay pathways, we analyzed the splicing status and putative AREs and Puf-binding sites of lncRNAs in the context of their stability. Similar to mRNAs, we find that spliced lncRNAs are more stable than single exon mRNAs (Narsai et al. 2007), and there are positive correlations between both the number of introns and the density of splice junctions per kb of ORF length and stability (Sharova et al. 2009). To investigate whether these factors known to affect coding transcript stability also impact the stability of noncoding RNAs, which would suggest common regulatory and decay pathways, we analyzed the splicing status and putative AREs and Puf-binding sites of lncRNAs in the context of their stability. Similar to mRNAs, we find that spliced lncRNAs are more stable than single exon transcripts ($P < 0.0001$) (Fig. 6A) and that single exon transcripts are over-represented among unstable transcripts ($t\frac{1}{2} < 2 \text{ h}$) ($P < 0.0001$) (Fig. 6B; Supplemental Fig. S11). However, unlike mRNAs (Supplemental Fig. S10), no correlation was found between the stability of spliced transcripts and the number of introns or density of splice junctions (Supplemental Fig. S11). Furthermore, no significant relationship was found between lncRNA stability and predicted ARE or Puf-binding sites (Supplemental Fig. S11), although the closeness to statistical significance for ARE sites ($P = 0.091$, Spearman correlation), suggests such a relationship might be present with a larger sample size. As expected, we did observe a negative relationship between the presence of these motifs and mRNA stability (Supplemental Fig. S10).

Utilizing our genome-wide lncRNA annotations, we examined other properties of lncRNAs that could impact stability. LncRNAs with a polyadenylation signal had higher stability than those transcripts that appeared internally primed ($P < 0.0001$) (Fig. 6C; Supplemental Fig. S11). We also identified positive correlations between the stability of lncRNAs and increases in transcript conservation and GC% percentage (Fig. 6D; Supplemental Fig. S11). These relationships were also identified in mRNAs (Supplemental Fig. S10). Although current long RNA structure prediction approaches are limited, GC% is a simple proxy for the potential of a RNA to fold into secondary structures due to the higher stability of GC base pairs. The positive relationship between GC% and stability suggests that lncRNAs with more structural elements are, perhaps not surprisingly, more stable.

Finally, we also investigated whether there were any characteristics of lncRNAs that could explain why they were less stable than mRNAs. Unexpectedly, we observed similar proportions of mRNAs and lncRNAs localized to the nucleus, with nuclear-enriched mRNAs also displaying lower stability than cytoplasmic or nonenriched transcripts ($P < 0.001$, one-way ANOVA). These results suggest it is not the frequent localization of lncRNAs to the nucleus that results in their lower stability relative to mRNAs; instead, the differential stability may be due to other RNA features. We find that many RNA characteristics that positively correlate with stability in lncRNAs and/or mRNAs, such as whether or not a transcript is spliced, the density of splice junctions, GC%, and degree of evolutionary conservation, have much lower values in lncRNAs compared to mRNAs (all $P < 0.0001$, Mann Whitney $t$-tests and $\chi^2$ tests). For example, the average intron density in lncRNAs is much lower than for mRNAs, which may explain why the correlation for lncRNAs was positive but not significant; i.e., too few lncRNAs have sufficient intron density to provide measureable stabilization, as is the case for mRNAs. Taken together, we find evidence that a number of sequence features known to affect mRNA stability also impact lncRNAs and provide some insight into why lncRNAs are, on average, less stable.

Comparison of lncRNA stability between mouse and human

We investigated the conservation and variability in lncRNA half-lives between mouse and human. Searching the stability micro-
arrays performed by Friedel et al. (2009) on human B cells and mouse 3T3 cells for probes corresponding to the genomic locations of lncRNAs from IncRNAdb (Amaral et al. 2011), we identified 11 lncRNAs with measured half-lives in both species (Supplemental Table S5). While most lncRNAs showed similar half-lives between the two species, four were significantly different, showing higher stability in human (all \( P < 0.001 \)) (Fig. 7A). For example, MALAT1, which is found in SC35 splicing speckles and plays a role in the regulation of splicing (Tripathi et al. 2010) was highly stable in human B cells, with a half-life of 16.5 h, compared to 3 h in mouse 3T3 cells. Investigation of Malat1 in mouse N2A cells by qPCR identified a half-life of 4 h (Supplemental Fig. S13), in good agreement with Friedel et al. (2009) but significantly shorter than determined previously in mouse embryonic fibroblasts (Bernard et al. 2010). Neat1 was also stable in human cells but unstable in mouse (investigated further below).

We recently reported on the extreme stability of the Zfas1 lncRNA, which is expressed from a bidirectional promoter with the Znf31 protein-coding gene (Askarian-Amiri et al. 2011) and showed no evidence of degradation after 16 h of transcriptional inhibition. Using the improved stable control genes, we extended this analysis to find that Zfas1 levels remain unchanged even after 32 h (Fig. 1B). This remarkably high level of stability may explain its high very expression level in N2A cells (top 0.5% of all expressed transcripts). In contrast, the stability of Zfas1 in mouse 3T3 cells and in human revealed much shorter half-lives of 1.7 and 3 h, respectively (Friedel et al. 2009). Friedel et al. (2009) did not block transcription to determine RNA half-lives; however, this result appears independent of the method used, as another study of mRNA half-lives in mouse embryonic stem cells using actinomycin D found the Zfas1 half-life to be 63 min (Sharova et al. 2009). Rather, these results suggest there can be large changes in lncRNA stability both within and between species and highlights the dynamic nature of lncRNA post-transcriptional regulation.

The architectural lncRNA Neat1 is highly unstable

Neat1 is a structural RNA involved in the formation and integrity of nuclear paraspeckles (Bond and Fox 2009; Sunwoo et al. 2009; Mao et al. 2011). Surprisingly, given its identification as a functional “architectural” RNA and similar to Friedel et al. (2009), Neat1 was very unstable with a half-life of <30 min by array and 15 min by qPCR (Fig. 7B). As Neat1 is unspliced and has short, \(-3.2 \text{ kb (Neat1} _v1/\text{Men epsilon)} \) and long, \(-20 \text{ kb (Neat1} _v2/\text{Men beta)} \) isoforms transcribed from a single promoter (Guru et al. 1997; Sunwoo et al. 2009), both the array and qPCR were quantifying the combined stability of the short and long isoforms (Fig. 7B,C). Neat1_v2, but not Neat1_v1, is able to rescue a Neat1 knockdown (Sasaki et al. 2009) and is required for paraspeckle formation in mice (Nakagawa et al. 2011), suggesting this isoform is more central to Neat1 function. Although qPCR specific to this isoform revealed it was significantly more stable than the combined short and long isoforms (\( P < 0.05 \)), the long isoform is still unstable with a half-life of 60 min (Fig. 7D,E).

To investigate whether the high instability of Neat1 affected the formation of paraspeckles, we performed RNA-protein FISH in N2A cells. This revealed only a few, small nuclear speckles within a minority of cells by RNA FISH, which was consistent with the lack of localization of the paraspeckle protein NONO to nuclear speckle structures (Fig. 7G; Supplemental Fig. S12). N2A cells are “undifferentiated,” and the up-regulation of Neat1 (and formation of paraspeckles) upon differentiation has been reported in other cell-type specific differentiation systems (Chen and Carmichael 2009; Sunwoo et al. 2009). To examine the possibility that Neat1 up-regulation may be partially post-transcriptional and that low stability may prevent proper paraspeckle formation, we investigated Neat1 stability in 3T3 cells, which have abundant paraspeckles (Fig. 7H; Supplemental Fig. S12). The half-lives of Neat1 (v1 and v2) and Neat1_v2 were calculated as 32 min (95% CI = 24 min–47.8 min) and 63 min (95% CI = 47.3 min–93 min), respectively, indicating that there was no difference in Neat1 stability between cells with and without paraspeckles. Subtracting the expression of Neat1_v2 from Neat1 (v1 and v2) revealed that Neat1_v1 was significantly less stable than the long isoform, with a half-life of 19.6 min (95% CI = 15.22 min–27.59 min) (Fig. 7F). Therefore, we conclude that the presence/absence of paraspeckles in these cells is not related to Neat1 stability. Furthermore, the highly unstable nature of Neat1 demonstrates that instability is not a barrier to lncRNA function and that, instead, the high turnover of Neat1 could contribute to the highly dynamic nature of paraspeckles (Mao et al. 2011).

Discussion

Contrary to some expectations, examination of lncRNA stability and comparison to that of protein-coding genes has revealed that lncRNAs are not generally unstable but rather show a wide variation in their stability profiles in a manner similar to mRNAs. In light of several studies that show remarkably specific expression profiles for lncRNAs in diverse tissues and development systems (Dinger et al. 2008; Guttman et al. 2010; Cabili et al., 2011), as well as a recent large-scale screen showing functions for many lncRNAs in embryonic stem cell differentiation (Guttman et al. 2011), the large variation in lncRNA stability is consistent with their functional diversity and is likely a reflection of their complex post-transcriptional regulation. Indeed, post-transcriptional regulation is particularly important for lncRNAs because, unlike protein-coding genes, they do not have any further translational and post-translational opportunities for regulation. We find that a number of lncRNA characteristics correlate with stability, including genomic location, subcellular localization, splicing, and GC percentage. Other characteristics, such as the density of exon junctions, had no measurable impact on lncRNAs despite providing the strongest correlation with the miRNA stability of those tested. LncRNA expression level also was not correlated with stability, suggesting that lncRNAs below the expression cutoff will not be generally unstable either, although this possibility cannot be completely discounted. Overall, we find that analysis of lncRNA sequence features is an effective means of gaining insight into factors underlying stability.

A large number of post-transcriptional regulatory pathways act by regulating RNA stability and degradation. Some, such as the nuclear and cytoplasmic exosomes, have been found to degrade lncRNAs (including mRNAs and NMD, and sometimes mediate decay (NMD)), act on lncRNAs is poorly understood. In Arabidopsis, putative lncRNAs can be regulated by NMD (Tykowski et al. 1996; Kurihara et al. 2009), a process thought to require a pioneer round of translation (Maquat et al. 2010), which could suggest “noisy” translation of lncRNAs. Recently, the first example of m6A regulation of lncRNAs was identified (Hansen et al. 2011), suggesting this process may be widespread. RNA-binding proteins can also affect RNA stability; for example, the presence of the exon-junction
Figure 7. Neat1 stability. (A) Comparison of lncRNA stabilities in mouse and human from Friedel et al. (2009). Error bars are standard deviations. Significant differences determined by two-way ANOVA using Bonferroni multiple comparisons. (*** \(P < 0.001\), (**** \(P < 0.0001\). (B) Transcript decay curve for Neat1 (both v1 and v2 isoforms) in N2A cells after blocking transcription with actinomycin D and measuring transcript remaining relative to Gapdh by qPCR. complex has been hypothesized to be responsible for the increased stability of mRNAs with a higher density of splice junctions (Sharova et al. 2009). Indeed, we find this appears to apply to IncRNAs, as spliced IncRNAs are more stable than those that are unspliced.

We find that a larger proportion of IncRNAs than mRNAs are unstable. Both our results and previous findings from mammals and yeast (Seidl et al. 2006; Berretta et al. 2008; van Dijk et al. 2011) have shown that low stability does not mean IncRNAs are non-functional. Instead, low stability can be important for regulating IncRNA function. For example, stability can determine where and when a IncRNA can perform its function, as exemplified by PHO84 antisense in yeast (Camblong et al. 2007). Furthermore, by not requiring translation to produce a functional gene product, IncRNAs, especially those acting in the nucleus, can function almost immediately after transcription (Dinger et al. 2009a) and so may not require a long half-life. In addition, unstable transcripts are very sensitive to changes in the level of transcription and respond quickly when transcription changes (Elkon et al. 2010; Rabani et al. 2011). Low stability, such as that observed in many transcription factor mRNAs, allows dynamic gene expression in response to environmental signals (both intra- and extracellular) that can activate or repress genes. A growing number of IncRNAs, have been found to interact with chromatin and chromatin modification complexes, and some have been shown to regulate gene expression (Dinger et al. 2008; Khalil et al. 2009; Zhao et al. 2010; Gutttman et al. 2011; Wang et al. 2011). It has previously been hypothesized that unstable IncRNA would be suitable for regulating gene expression (Dinger et al. 2009a), and indeed, we find that RNAs which associate with chromatin binding proteins exhibit lower stability, suggesting that IncRNA “transcription factors” with analogous properties to their coding mRNA counterparts may exist.

Consistent with our finding that low stability does not mean lack of function, we identify the nuclear paraspeckle component Neat1 as among the least stable IncRNAs. Nuclear paraspeckles are highly dynamic nuclear subdomains (Mao et al. 2011). Transcription of Neat1 is required to both nucleate and maintain paraspeckles at the Neat1 locus, with paraspeckles quickly disassembling upon inhibition of Neat1 transcription (Mao et al. 2011). The unstable nature of the Neat1 isoforms could contribute to this dynamic regulation, as paraspeckles formed around a highly stable RNA would likely be less susceptible to such quick degradation. In human, Neat1 appears to be more stable than in mouse (Friedel et al. 2009; Sasaki et al. 2009; Sunwoo et al. 2009), with unknown consequences for Neat1 function and paraspeckle dynamics.

Although occurring at a lower incidence than mRNAs, we also identified a number of highly stable IncRNAs. Apart from the recently identified Zfs1 (Askarian-Amiri et al. 2011), which was too stable for array-based half-life modeling but the stability of which has been confirmed by qPCR, few of these IncRNAs have been characterized. Highly stable mRNAs often encode highly stable proteins with “housekeeping” functions, such as those in central metabolism, which do not require dynamic regulation for their proper function (Schwanhausser et al. 2011). Similarly, highly stable IncRNAs may serve “housekeeping” roles. The existence of highly stable IncRNAs also suggests that some IncRNAs have evolved to avoid degradation through various mechanisms, such as secondary structure and interactions with RNA-binding proteins, about which little is known.

Despite the large impact actinomycin D treatment has on cells, previous genomic scale studies have shown good agreement between actinomycin D treatment and other methods, which do not require transcriptional blockade (Dolken et al. 2008; Friedel et al. 2009; Rabani et al. 2011; Schwanhausser et al. 2011), with the proviso that the actinomycin D time course is of sufficient duration (>6 h) to determine the half-life of stable transcripts (Friedel et al. 2009). Although actinomycin D treatment can stabilize transcripts globally, the rank order of transcript stabilities appears relatively unchanged (Rabani et al. 2011; Schwanhausser et al. 2011), supporting the validity of our conclusions regarding IncRNA stability.

The increasing availability of genome-wide technologies such as microarrays, high-throughput proteomics and next-generation sequencing has led to an explosion of studies featuring massive data sets. However, there has been minimal innovation with respect to the visualization of and accessibility to genome-scale data sets, and it is typically a complex process to extract and navigate the data sets associated with such studies. To address this issue, here we have presented our data set using QAPgrid clustering and combined this with an interactive navigation system based on Google Maps and an easily searchable database. As a result, users can become oriented within the data at various levels, such as by browsing the stability profiles or by searching for clusters that contain a particular transcript. In addition to providing convenient access to the data presented here, such an interface can be readily adapted to other genome-scale data sets. We also suggest that such advances in data dissemination are important to provoke further innovation in this important area, which we anticipate will become an increasingly essential component in any study presenting genome-scale data.

Attempts to dissect the regulatory circuitry of a biological system have increasingly led to the application and integration of various “omics” approaches. Our data and that of others suggest that there are significant correlations between stability profile and function (Sharova et al. 2009; Rabani et al. 2011; Schwanhausser et al. 2011). Furthermore, transcripts clustered into the same decay profiles (despite large differences in actual transcript expression levels) may be regulated by the same post-transcriptional regulatory pathways and/or contain similar regulatory sequences. Given the substantial complexity of the mammalian transcriptome, which continues to grow with increasingly sensitive technology, there is an increasing need for techniques to aid in the functional annotation of novel transcripts and variant isoforms, which now by far exceed the number of transcripts for which a function has been assigned. We suggest that stability profiling provides an important facet in the characterization of the transcriptome in a given biological system and is an important consideration in the ranking of candidate transcripts to pursue for more detailed functional studies.

Methods

Cell culture and RNA extraction

Mouse Neuro-2a (N2A) neuroblastoma cells (ATCC number CCL-131) and NIH-3T3 cells were cultured at 37°C, 5% CO₂, in DMEM plus 10% newborn calf serum and penicillin/streptomycin. For stability experiments, cells were grown to ~50% confluency before RNA polymerase activity was blocked with 10 μg/mL actinomycin D (Sigma) in DMSO. Control cells were treated with DMSO alone. Transcriptional inhibition of N2A cells was conducted for 32 h, with cells harvested at time zero (0 h) and after 30 min, 2, 4, 8, 16, and 32 h. Inhibition of 3T3 cells was conducted for 24 h with harvesting at time zero (0 h) and after 30 min, 2, 4, 8, and 24 h. Cells were collected by trypsinization and total RNA extracted.
up-regulated during later time points similar to Zfas1 (Askarian-Amiri et al. 2011) and Myc (Myc). The average expression of this group of seven genes between each time point was calculated, set to zero, and the probe intensity data was scaled proportionately. Summary statistics for each probe including expression values, fold change, adjusted P-values, and Bayesian (B) statistics were calculated using LIMMA. An eBays (B statistic) prior of 25% was used. An appropriate expression cutoff was empirically determined by examining the ability of the microarrays to detect transcriptional decay as the 0-h expression level decreased and selecting a 0-h value which was sufficiently above background to allow accurate half-lives to be calculated. Raw and normalized microarray data is available at the ArrayExpress Data Warehouse (EMBL-EBI; ArrayExpress accession number E-MTAB-961).

Half-life calculations

Half-lives were calculated for probes above the expression cut-off of 25. Probe responses ranged from fast degradation to unchanged. Decay profiles were modeled by one-phase exponential decay (constraints: plateau > 0, K > 0) and/or linear decay using non-linear least squares regression using R (www.r-project.org). Probes showing statistically decreased expression were modeled with both one-phase decay and linear decay. Only fits with an R² > 0.7 were utilized. Where both models produced good fits, the model producing the better R² value was chosen. The remaining probes were modeled with linear decay only. Half-lives were calculated from a filtered set of probes shown by an F-test to have a significantly negative slope and with R² > 0.7.

Clustering

Unsupervised hierarchical clustering was performed using cluster3 software (de Hoon et al. 2004). Clustering of all lnCRNAs above the expression cut-off used the command line parameters -g 4 -e 2 -m m, which specifies the pairwise complete linkage method for the clustering and Pearson correlation for both the microarray and probe clustering. Normalized probe intensities are expressed relative to 1 at time 0 h. Clustering of lnCRNA genomic location classes used the command line parameters -cg a -g 0 -e 5 -s -m m, which centers each time point by subtracting the mean, utilizing the pairwise complete linkage method for the clustering and Spearman’s rank correlation for the lnCRNA classes only. The resulting clusters were visualized using Java TreeView (Saldanha 2004).

The unsupervised graph-based clustering and visualization of decay profiles was performed using QAPgrid. The clustering approach and several illustrative examples on different data sets have been published previously (Inostroza-Ponta et al. 2011). The clustering algorithm receives as input the time expression values of 14,987 probe sets. After computing the Pearson correlation values for all pairs of probe sets (x,y)—which we denote as \( r(x,y) \)—a distance matrix is calculated according to the formula

\[
d(x,y) = 1 - r(x,y)
\]

The clustering algorithm (MSTkNN) does not require user-defined parameters such as the number of clusters or number of elements per cluster. According to its built-in stopping criteria, it has returned 152 clusters. In turn, another matrix of distances is computed between each of these 152 clusters (for details of calculations, see Inostroza-Ponta et al. [2011]). With the input of these two matrices, we use a metaheuristic (a memetic algorithm) to solve a quadratic assignment problem defined over a grid. We obtain a layout in which, at least globally, highly similar expression patterns among clusters and super-clusters are likely to be in close proximity in the final figure produced by the method. For the figures, each of the cluster’s profile graphs was produced using stacked bar plots using R (www.r-project.org). To allow integration between half-lives, clustering, and transcript annotations, each cluster was linked to a list of the probes contained in the cluster, along with half-life and annotation information. Cluster enrichment analysis was performed with gprofiler and GATHER (Chang and Nevins 2006; Medina et al. 2010; Reimand et al. 2011).

Annotation of coding and noncoding RNA transcripts

Protein-coding gene structures were based on UCSC Known Genes (Fujita et al. 2011) and Refseq (Pruitt et al. 2009) as of April 2011. Noncoding transcripts were derived from the “All mRNA” track in the UCSC Genome Browser (Fujita et al. 2011) and were defined as noncoding if they had <5% overlap with protein-coding exons and an ORF less than 100 amino acids. PhyloCSF (Lin et al. 2011) was used to filter putative lnCRNAs, and any transcripts with a score of 50 (or above) were defined as protein coding. A classification as protein coding was overridden if the transcript was found in lnCRNAdb (Amaral et al. 2011) or had been identified as binding to chromatin regulatory proteins (Guttman et al. 2011). Genomic locations of lnCRNAs were defined as follows: Head-to-head transcripts from bidirectional promoters were defined as transcripts that originate from the antisense strand within 1 kb upstream of or
of log₂ ≥ 7 were defined as expressed. Enrichment in either compartment was defined as ≥two-fold expression enrichment, $P$-value < 0.05, B-statistic > 0. Raw and normalized microarray data is available at the ArrayExpress Data Warehouse (EMBL-EBI; ArrayExpress accession number E-MTAB-952).

qPCR
Reverse transcription was carried out with the SuperScript III cDNA synthesis kit (Invitrogen) using random hexamers. Quantitative real-time PCR (qPCR) was performed using SYBR Green PCR Master Mix and real time cyclers (Applied Biosystems). Relative quantification to a stability control (Gapdh or AlpSε) was performed for stability qPCRs. At least three biological replicates were performed for all transcriptionally inhibited time courses. Decay profiles were graphed and half-lives calculated using GraphPad Prism (GraphPad Software) as per Askarian-Amiri et al. (2011). The 0-h time point expression level was set to 100%, and the percentage of transcript remaining at each time point calculated. Half-lives were calculated by non-linear regression with a least squares fit (plateau > 0, k > 0), using one-phase exponential decay, or, when no decay was observed, a linear line. Primer sequences are provided in Supplemental Table S6.

Absolute quantification was performed for fractionation samples. Equivalent micrograms of nuclear and cytoplasmic RNAs used for qPCR were converted to cell equivalents by multiplying the cytoplasmic expression level by the cytoplasmic/nuclear RNA ratio calculated from the RNA extraction yields. Nuclear/cytoplasmic enrichment ratios were calculated from three biological replicates.

Western blotting
Protein lysate concentrations were measured using the Bradford assay and then run on 12.5% polyacrylamide gels, which were Coomassie-stained to confirm equal loadings. Proteins from SDS-PAGE gels were transferred to PVDF membrane using a semi-dry procedure. Membranes were blocked overnight in 5% milk powder. Primary and secondary antibody incubations were carried out for 2 h. GAPDH (1:4000 dilution) (R&D systems), HISTONE H3 (1:1000), anti-rabbit HRP (1:5000) (Cell Signaling Technologies). Proteins were visualized using ECL (GIBCO).

FISH
N2A and NIH-3T3 cells were seeded onto microscope cover slips and grown until ~80% confluent. Cover slips were incubated in Extraction buffer (100 mM NaCl, 300 mM sucrose, 10 mM PIPES, 3 mM MgCl₂, 0.5% Triton, and 10 mM vanadyl ribonucleoside complex, VRC) for 1 min, washed with 4% PFA/PBS at 4°C for 40 min, fixed with 4% PFA/PBS at 4°C overnight. Cover slips were washed three times in 1× SSC, then incubated in 1× SSC/0.4% BSA and incubated on each cover slip at 37°C for 1 h, followed by washing in 4× SSC, then 4× SSC/0.1% Triton, then again in 4× SSC. NOONO mouse monoclonal antibody (Souquere et al. 2010) was diluted 1:500 in PBS/0.05% Tween-20 and incubated on cover slips at room temperature for 1 h, followed by three washes with PBS/0.05% Tween-20, then

N2A fractionation arrays
N2A nuclear and cytoplasmic fractions were isolated using a variation of a procedure described previously (Andersen et al. 2002). Cells were trypsinized, washed twice in ice cold PBS, and resuspended in low salt buffer (10 mM HEPES, pH 7.9, 10 mM KCl, 1.5 mM MgCl₂, 0.5 mM DTTO) ice to swell (swelling was confirmed using a phase contrast microscope). Cells were transferred to an ice cold Dounce homogenizer and homogenized until at least 95% of cells were burst, but nuclei were still intact. Homogenate was centrifuged at 220g for 5 min at 4°C to separate the cytoplasmic fractions and nuclear-enriched pellets. The pellets were resuspended in 0.25 M sucrose, 10 mM MgCl₂ buffer and overlayed on 0.88 M sucrose, 0.5 mM MgCl₂ buffer, then were centrifuged at 3000g for 15 min at 4°C to obtain pure nuclei. RNA was extracted, and three biological replicate microarrays performed and normalized as described previously (Askarian-Amiri et al. 2011). An eBayes (B-statistic) prior of 15% was used. Data was loaded and analyzed using NRED (Dinger et al. 2009b). Probes with expression...
probed with anti-mouse-TRITC secondary antibody (Jackson Immuno Research Laboratories) diluted 1:250 in PBS/0.05% Tween-20 for 1 h, followed by three washes in PBS/0.05% Tween-20. Cover slips were stained with DAPI (Sigma), mounted with Vectashield (Vector Laboratories), and z-stacks obtained using a Nikon TiE fluorescent microscope.

Paraspeckle quantification
Maximum projections of deconvolved z-stacks of NIH-3T3 cell nuclei (N = 18) and N2A cell nuclei (N = 31) from Neat1 FISH with NONO and DAPI containing were converted to grayscale in each of the three fluorescent channels used. The images were then analyzed using CellProfiler (www.cellprofiler.org) using a modification of the “Speckle counting” pipeline (available on request) that is given on the CellProfiler website (http://www.cellprofiler.org/examples.shtml).

Data access
Raw microarray raw data is available at the ArrayExpress Data Warehouse (EMBL-EBI: ArrayExpress accession numbers E-MTAB-952 and E-MTAB-961). All normalized stability and localization array data is available online at http://stability.matticklab.com and/or in Supplemental Tables S1 and S2.

Competing interest statement
M.E.D. and J.S.M. are license holders of the NCode ncRNA microarrays (Life Technologies).
